Coronal heating and wind acceleration by nonlinear Alfvén waves –
global simulations with gravity, radiation, and conduction

Abstract. We review our recent results of global one-
dimensional (1-D) MHD simulations for the acceleration of
solar and stellar winds. We impose transverse photospheric
motions corresponding to the granulations, which generate
outgoing Alfvén waves. We treat the propagation and dissi-
pation of the Alfvén waves and consequent heating from the
photosphere by dynamical simulations in a self-consistent
manner. Nonlinear dissipation of Alfvén waves becomes
quite effective owing to the stratification of the atmosphere
(the outward decrease of the density). We show that the
coronal heating and the solar wind acceleration in the open
magnetic field regions are natural consequence of the foot-
point fluctuations of the magnetic fields at the surface (pho-
tosphere). We find that the properties of the solar wind sen-
sitively depend on the fluctuation amplitudes at the solar sur-
face because of the nonlinearity of the Alfvén waves, and
that the wind speed at 1 AU is mainly controlled by the field
strength and geometry of flux tubes. Based on these results,
we point out that both fast and slow solar winds can be ex-
plained by the dissipation of nonlinear Alfvén waves in a
unified manner. We also discuss winds from red giant stars
driven by Alfvén waves, focusing on different aspects from
the solar wind.

1 Introduction

The Alfvén wave, generated by the granulations or other sur-
face activities, is a promising candidate operating in the heat-
ing and acceleration of solar winds from coronal holes. It can
travel a long distance so that the dissipation plays a role in the
heating of the solar wind plasma as well as the lower coro-
nal plasma, in contrast to other processes, such as magnetic
reconnection events and compressive waves, the heating of
which probably concentrates at lower altitude.

Most of the power of injected Alfvén waves is supposed
to be peaked around 5 min (∼0.003 Hz) in the sun, which
is, far below the ion cyclotron frequency (∼10⁴ Hz in the
corona), in the MHD regime. When considering such low-
frequency Alfvén waves in solar and stellar atmospheres, the
stratification of the density due to the gravity is quite im-
portant because the variation scale of the density, and ac-
cordingly Alfvén speed, is comparable to or shorter than the
wavelengths; the WKB approximation is no longer applica-
able. Also, the amplitude of the wave is amplified because
of the decrease of the density so that waves easily become
nonlinear.

A number of attempts have been carried out to investigate
nonlinear Alfvén waves in stratified solar winds in 1-D (Lau
and Siregar, 1996; Boynton and Torkelsson, 1996) and 2-D
(Ofman and Davila, 1997, 1998; Grappin et al., 2002), and by
multi-fluid treatments (Ofman, 2004). These studies nicely
explain observations by suitable choices of perturbation am-
plitude at the inner boundary in the corona. However, the
input amplitude at the coronal base is not accurately deter-
mained from observations. The photosphere is a more suit-
able inner boundary for theoretical calculations because the
physical properties are precisely obtained from various ob-
servations. The density of the coronal base is 8–9 orders of
magnitude smaller than that of the photosphere. The dissi-
pation and reflection of Alfvén waves are important in the
chromosphere and the transition region, which lie between
the photosphere and corona. Furthermore, from the chromo-
sphere to the low corona, radiation cooling plays a role in the
energetics. Then, to consistently treat the heating of the gas,
the radiative loss needs to be properly taken into account.

Recently, we have extensively studied the heating and ac-
celeration of solar and stellar winds by self-consistent MHD
simulations with gravity and cooling (Suzuki and Inutsuka,
2005, 2006; hereafter SI06; Suzuki, 2007). By reviewing
our recent results, we introduce various aspects of nonlinear Alfvén waves in the Sun and stars to the geophysics community.

2 Set-up

We consider 1-D open flux tubes which are super-radially open, measured by heliocentric distance, \( r \). The simulation regions are from the photosphere (\( r=1 R_\odot \)) with density, \( \rho=10^{-9} g cm^{-3} \), to \( 65 R_\odot \) (0.3 AU) or \( \approx 20 R_\odot \) (0.1 AU), where \( R_\odot \) is the solar radius. Radial field strength, \( B_r \), is given by conservation of magnetic flux as

\[
B_r r^2 f (r) = \text{const},
\]

where \( f (r) \) is a super-radial expansion factor. We adopt the same function as in Kopp and Holzer (1976) for \( f (r) \) (see SI06 for detail).

We input the transverse fluctuations of the field line by the granulations at the photosphere, which excite Alfvén waves. In this paper we only show results of linearly polarized perturbations with power spectrum proportional to \( 1/\nu \), where \( \nu \) is frequency (see SI06 for circularly polarized fluctuations with different spectra). Amplitude, \( \langle dv_{\perp,0} \rangle \), at the photosphere is chosen to be compatible with the observed photospheric velocity amplitude \( \sim 1 \text{ km s}^{-1} \) (Holweger et al., 1978). At the outer boundaries, non-reflecting condition is imposed for all the MHD waves, which enables us to carry out simulations for a long time until quasi-steady state solutions are obtained without unphysical wave reflection.

We dynamically treat the propagation and dissipation of the waves and the heating and acceleration of the plasma by solving ideal MHD equations with the relevant physical processes (paper I):

\[
\frac{d\rho}{dt} + \rho \frac{\partial}{\partial r} (r^2 f v_r) = 0,
\]

\[
\frac{\rho dv_r}{dt} = - \frac{\partial p}{\partial \nu} - \frac{1}{8\pi r^2 f} \frac{\partial}{\partial r} (r^2 f B_{\perp}^2)
\]

\[
\frac{\rho d^2 v_r}{dt^2} = \frac{\rho v_r^2}{2r^2 f} \frac{\partial}{\partial r} (r^2 f) - \rho \frac{GM_\odot}{r^2},
\]

\[
\frac{\rho d}{dt} (r \sqrt{f} v_\perp) = B_r \frac{\partial}{\partial r} (r \sqrt{f} B_{\perp}).
\]

3 Results

3.1 High-speed solar wind

Figure 1 plots the initial condition (dashed lines) and the results after the quasi-steady state condition is achieved at \( t=2573 \text{ min} \) (solid lines), compared with recent observations of fast solar winds. From top to bottom, \( v_r \text{ (km s}^{-1}) \), \( T(\text{K}) \), mass density, \( \rho(\text{g cm}^{-3}) \), and rms transverse amplitude, \( \langle dv_{\perp} \rangle \text{(km s}^{-1}) \) are plotted. As for the density, we compare our result with observed electron density, \( N_e \), in the corona. These variables are averaged for 3 min to incorporate observational exposure time. We set the transverse fluctuation, \( \langle dv_{\perp,0} \rangle \approx 0.7 \text{ km s}^{-1} \), and field strength, \( B_{r,0} = 161 \text{ G} \) at the photosphere, and the total superradial expansion factor, \( f_{\text{tot}} = 75 \) (see Table 1). While our model adopts one-fluid approximation, namely all the species are assumed to be the same temperature and velocity, we think that the temperature represents electrons rather than ions because the temperature is mainly controlled by electron thermal conduction in the corona, and that the velocity represents protons which carry most of the mass.

Figure 1 shows that the initially cool and static atmosphere is effectively heated and accelerated by the dissipation of the Alfvén waves. The sharp transition region which divides the cool chromosphere with \( T \sim 10^4 \text{ K} \) and the hot corona with \( T \sim 10^6 \text{ K} \) is formed owing to a thermally unstable region.
Fig. 1. Results of fast solar wind with observations in polar regions. From top to bottom, outflow speed, $v_r$ (km s$^{-1}$), temperature, $T$ (K), density in logarithmic scale, $\log(\rho)$ (g cm$^{-3}$)), and rms transverse amplitude, $\langle dv_\perp \rangle$ (km s$^{-1}$) are plotted. Observational data in the third panel are electron density, $\log(N_e)$ which is to be referred to the right axis. Dashed lines indicate the initial conditions and solid lines are the results at $t=2573$ min. In the bottom panel, the initial value ($\langle dv_\perp \rangle=0$) does not appear. First: Green vertical error bars are proton outflow speeds in an interplume region by UVCS/SoHO (Teriaca et al., 2003). Dark blue vertical error bars are proton outflow speeds by the Doppler dimming technique using UVCS/SoHO data (Zangrilli et al., 2002). A dark blue open square with errors is velocity by IPS measurements averaged in 0.13–0.3 AU of high-latitude regions (Kojima et al., 2004). Light blue data are taken from Grall et al. (1996); crossed bars are IPS measurements by EISCAT, crossed bars with open circles are velocity by VLBA measurements, and vertical error bars with open circles are data based on observation by SPARTAN 201-01 (Habbal et al., 1994). Second: Pink circles are electron temperatures by CDS/SoHO (Fludra et al., 1999). Third: Circles and stars are observations by SUMER/SoHO (Wilhelm et al., 1998) and by CDS/SoHO (Teriaca et al., 2003), respectively. Triangles (Teriaca et al., 2003) and squares (Lamy et al., 1997) are observations by LASCO/SoHO. Fourth: Blue circles are non-thermal broadening inferred from SUMER/SoHO measurements (Banerjee et al., 1998). Cross hatched region is an empirical constraint of non-thermal broadening based on UVCS/SoHO observation (Esser et al., 1999). Green error bars are transverse velocity fluctuations derived from IPS measurements by EISCAT (Canals et al., 2002).

Fig. 2. $r-t$ diagrams for $v_r$ (upper-left), $\rho$ (lower-left), $v_\perp$ (upper-right), and $B_\perp/B_r$ (lower-right.) The horizontal axises cover from $R_\odot$ to 15$R_\odot$, and the vertical axises cover from $t=2570$ min to 2600 min. Dark and light shaded regions indicate positive and negative amplitudes which exceed certain thresholds. The thresholds are $dv_r=\pm 96$ km/s for $v_r$, $d\rho/\rho=\pm 0.25$ for $\rho$, $v_\perp=\pm 180$ km/s for $v_\perp$, and $B_\perp/B_r=\pm 0.16$ for $B_\perp/B_r$, where $d\rho$ and $dv_r$ are differences from the averaged $\rho$ and $v_r$. Arrows on the top panels indicate characteristics of Alfvén, slow MHD and entropy waves at the respective locations.

around $T \sim 10^5$ K in the radiative cooling function (Landini and Monsignori-Fossi, 1990). The hot corona streams out as the transonic solar wind. The simulation naturally explains the observed trend quite well.

The heating and acceleration of the solar wind plasma in inner heliosphere is done by the dissipation of Alfvén waves. Here we inspect waves in more detail. Figure 2 presents contours of amplitude of $v_r$, $\rho$, $v_\perp$, and $B_\perp/B_r$ in $R_\odot \leq r \leq 15R_\odot$ from $t=2570$ min to 2600 min. Red (blue) shaded regions denote positive (negative) amplitude. Above the panels, we indicate the directions of the local 5 characteristics, two Alfvén, two slow, and one entropy waves at the respective positions. Note that the fast MHD and Alfvén modes degenerate in our case (wave vector and underlying magnetic field are in the same direction), so we simply call the innermost and outermost waves Alfvén modes. In our simple 1-D
presents the dissipation of the waves more quanti-

tatively. It plots the following quantities,

\[
S_c = \rho \delta v^2 \frac{(v_r + v_{ph})^2}{v_{ph}} \frac{r^2 f(r)}{r_c^2 f(r_c)},
\]

of outgoing Alfvén, incoming Alfvén, and outgoing slow MHD (sound) waves, where \( \delta v \) and \( v_{ph} \) are amplitude and phase speed of each wave mode. \( S_c \) is an adiabatic constant in unit of energy flux derived from wave action (Jacques, 1977). For the incoming Alfvén wave, we plot the opposite sign of \( S_c \) so that it becomes positive in the sub-Alfvénic region. The outgoing and incoming Alfvén waves are decomposed by correlation between \( v_r \) and \( B_\perp \). Extraction of the slow wave is also from fluctuating components of \( v_r \) and \( \rho \).

Figure 3 clearly illustrates that slow MHD waves as well as incoming Alfvén waves are nonlinearly generated, which play a role in the heating and acceleration of the solar wind plasma. Then, the outgoing Alfvén waves dissipate quite effectively; \( S_c \) becomes only \( \sim 10^{-3} \) of the initial value at the outer boundary. Figure 3 also shows that a sizable amount is reflected back downward below the coronal base (\( r-R_\odot < 0.01 R_\odot \)), which is clearly illustrated as the incoming Alfvén wave following the outgoing component with slightly smaller level. This is because the wave shape is considerably deformed owing to the steep density gradient; a typical variation scale (\( < \times 10^5 \) km) of the Alfvén speed becomes comparable to or even shorter than the wavelength (\( \times 10^5 - 10^6 \) km). Although the energy flux, \( \sim 5 \times 10^{15} \text{erg cm}^{-2} \text{s}^{-1} \), of the outgoing Alfvén waves \( (S_c) \) in the static region is equivalent with the energy flux which penetrates into the corona is only \( \sim 15\% \) of the input value, it satisfies the requirement for the energy budget in the coronal holes (Withbroe and Noyes, 1977).

The processes discussed here are the combination of the direct mode conversion to the compressive waves and the parametric decay instability due to three-wave (outgoing Alfvén, incoming Alfvén, and outgoing slow waves) interactions (Goldstein, 1978; Terasawa et al., 1986) of the Alfvén waves. Although they are not generally efficient in the homogeneous background since they are the nonlinear mechanisms, the density gradient of the background plasma totally changes the situation. Owing to the gravity, the density rapidly decreases in the corona as \( r \) increases, which results in the amplification of the wave amplitude so that the waves easily become nonlinear. Furthermore, the Alfvén speed varies a lot due to the change of the density even within one wavelength of Alfvén waves with periods of minutes or longer. This leads to both variation of the wave pressure in one wavelength and partial reflection through the deformation of the wave shape (Moore et al., 1991). The dissipation is greatly enhanced by the density stratification, in comparison with the case of the homogeneous background. Thus, the low-frequency Alfvén waves are effectively dissipated, which results in the heating and acceleration of the coronal plasma.

Before closing this section, it should be noted that the above discussion is based on the 1-D simulation. In realistic 3-D treatments, various other dissipation channels become effective, which will be discussed in Sect. 4.
3.2 Dependence on $d v$

We study dependences on the amplitudes of the input fluctuations at the photosphere. We compare the results of larger $\langle dv_{\perp,0} \rangle = 1.4 \text{ km s}^{-1}$ and smaller $\langle dv_{\perp,0} \rangle = 0.4 \text{ km s}^{-1}$ and $0.3 \text{ km s}^{-1}$ cases with the fiducial case $\langle dv_{\perp,0} \rangle = 0.7 \text{ km s}^{-1}$ in Fig. 4. Note in the case of $\langle dv_{\perp,0} \rangle = 0.3 \text{ km s}^{-1}$ quasi steady-state behavior is not achieved, and the density and temperature decrease with time as explained later.

The maximum temperature of $\langle dv_{\perp,0} \rangle = 0.4 \text{ km s}^{-1}$ case is $\approx 5 \times 10^5 \text{ K}$, which is cooler than the usual corona. The density is much lower than the fiducial case by 1–2 orders of magnitude because the sufficient mass cannot supply into the corona by the chromospheric evaporation owing to the low temperature; the evaporation is drastically suppressed as $T$ decreases since the conductive flux $F_C \propto T^{5/2} \frac{dT}{dr}$ sensitively depends on $T$. As a result, the mass flux ($\rho v_r$) becomes more than an order of magnitude lower than that of the present solar wind. These tendencies are more extreme in the $\langle dv_{\perp,0} \rangle = 0.3 \text{ km s}^{-1}$ case; the coronal temperature and density become further low in the case of $\langle dv_{\perp,0} \rangle = 0.3 \text{ km s}^{-1}$; $T \approx 2 \times 10^5 \text{ K}$ and the density in the corona and solar wind is smaller by 3 orders of magnitude than the fiducial case.

This behavior can be understood by the wave dissipation. The Alfvén speed ($= B/\sqrt{4\pi \rho}$) is larger in a smaller $\langle dv_{\perp,0} \rangle$ case due to the lower density and the nonlinearity, $\langle dv_{\perp,0} \rangle / v_A$, becomes weaker. As a result, the final energy flux of the solar wind at 0.1 AU, mostly consisting of the kinetic energy $\langle \rho v_r^2 \rangle$, becomes further smaller compared to the difference of input energy flux.

Once the coronal density starts to decrease, a positive feedback operates. Namely, the decrease of the density leads to weaker non-linearity of the Alfvén waves, which reduces the plasma heating by the wave dissipation. This decreases the coronal temperature, and further reduces the coronal density by the suppression of the chromospheric evaporation. This takes place in the case of $\langle dv_{\perp,0} \rangle = 0.3 \text{ km s}^{-1}$ so that the coronal density and temperature continue to decrease at later time, instead of maintaining steady corona and solar wind.

Our results show that $\langle dv_{\perp,0} \rangle \gtrsim 0.4 \text{ km s}^{-1}$ is the criterion of the photospheric fluctuations for the formation of the stable hot plasma. To get the maximum coronal temperature $\gtrsim 10^6 \text{ K}$, $\langle dv_{\perp,0} \rangle \gtrsim 0.7 \text{ km s}^{-1}$ is required. Otherwise if $\langle dv_{\perp,0} \rangle \lesssim 0.3 \text{ km s}^{-1}$, the low-frequency Alfvén waves cannot maintain the hot corona, and the solar wind mass flux becomes drastically small.

Larger $\langle dv_{\perp,0} \rangle$ gives larger coronal density. The initial increase of the temperature starts from a deeper location around $r \approx 0.005 R_\odot$ than the other cases. Thanks to this, a decrease of the density is slower (larger pressure scale height) so that the density around $r = 0.01 R_\odot$ is two orders of magnitude larger than that of the case with $\langle dv_{\perp,0} \rangle = 0.7 \text{ km s}^{-1}$. However, the temperature decreases slightly instead of a monotonical increase; it cannot go over the peak of the radiative cooling function at $T \lesssim 10^5 \text{ K}$ (Landini and Monsignori-Fossi, 1990) because the radiative loss is efficient owing to the large density. The second increase of the temperature begins from $r \approx 0.03 R_\odot$ and above there the corona is formed. The coronal density and temperature are larger than those in the case with $\langle dv_{\perp,0} \rangle = 0.7 \text{ km s}^{-1}$. In particular the density in the outer region is 10 times larger, and the mass flux of the solar wind is larger by the same extent.

3.3 Solar wind speed

It is widely believed that field strength and geometry of open flux tubes are important parameters that control the solar wind speed. Wang and Sheeley (1990, 1991) showed that the solar wind speed at $\sim 1 \text{ AU}$ is anti-correlated with $f_{\text{tot}}$ from their long-term observations as well as by a simple theoretical model. Ofman and Davila (1998) showed this tendency by time-dependent simulations as well. Fisk et al. (1999) claimed that the wind speed should be positively correlated with $B_{\text{r,0}}$ by a simple energetics consideration.

Kojima et al. (2005) have found that the solar wind velocity is better correlated with the combination of these two
parameters, \( B_{r,0}/f_{tot} \), than \( 1/f_{tot} \) or \( B_{r,0} \) from the comparison of the outflow speed obtained by their interplanetary scintillation measurements with observed photospheric field strength (Fig. 5). Suzuki (2004), SI06 and Suzuki (2006) also pointed out that \( B_{r,0}/f_{tot} \) should be the best control parameter provided that the Alfvén waves play a dominate role in the coronal heating and the solar wind acceleration. This is because the nonlinearity of the Alfvén waves, \( \langle dv_{A,+}\rangle/v_A \) is controlled by \( v_A \propto B_r \propto B_{r,0}/f_{tot} \) in the outer region where the flux tube is already super-radially open. Wave energy does not effectively dissipate in the larger \( B_{r,0}/f_{tot} \) case in the subsonic region because of relatively small nonlinearity and more energy remains in the supersonic region. In general, energy and momentum inputs in the supersonic region gives higher wind speed, while those in the subsonic region raises the mass flux (\( \rho v_r \)) of the wind by an increase of the density (Lamers and Cassinelli, 1999). This indicates that the solar wind speed is positively correlated with \( B_{r,0}/f_{tot} \).

Suzuki (2006) further derived a relation between the solar wind speed, \( v_{1AU} \), at 1 AU and surface properties from a simple energetics argument:

\[
v_{1AU} = \left[ 2 \times \frac{R_\odot^2}{4\pi (\rho v_r^2)_{1AU}} \frac{B_{r,0}}{f_{tot}} \langle dB_{\perp}, dv_{\perp}\rangle_{\odot} \right]^{1/2}
\]

\[
+ \frac{\gamma}{\gamma - 1} \frac{GM_\odot}{R_\odot} \left[ 5.9 \left( \frac{1}{\gamma - 1} \right) \frac{B_{r,0}}{f_{tot}} \left( \frac{b}{10^5}\right) \right]
\]

\[
+ 3.4 \left( \frac{\gamma}{1.1} \right) \left( \frac{0.1}{\gamma - 1} \right) \left( \frac{T_C}{10^6(K)} \right) - 4.2 \right]^{1/2}
\]

where we have the three free parameters, surface amplitude, \( \langle dB_{\perp}, dv_{\perp}\rangle_{\odot} \), effective coronal temperature, \( T_C \), and ratio of specific heats, \( \gamma \). In the equation, these parameters are evaluated by the standard values, which should be used for actual prediction of wind speed. The first term is the contribution from Alfvén waves, the second term represents net heating minus cooling due to radiation loss and thermal conduction, and the third term is the gravitational loss. The first term, due to Alfvén waves, exhibits the dependence on \( B_{r,0}/f_{tot} \), which reflects the Alfvén waves in expanding flux tubes. Figure 5 shows the prediction of Eq. (8), in comparison with the observation using interplanetary scintillation measurements by Kojima et al. (2005). The observed data are nicely explained by the relation based on the simple energetics.

3.4 Unification of high/low-speed solar winds

Based on our studies we can infer the suitable \( \langle dv_{\perp,0}\rangle \) and \( B_{r,0}/f_{tot} \) for the slow solar wind by comparing with those of the fast wind: The slow wind requires larger \( \langle dv_{\perp,0}\rangle \) and smaller \( B_{r,0}/f_{tot} \) than the fast wind. The adopted parameters are summarized in Table 1.

Figure 6 presents the results of fast (dashed lines) and slow (solid lines) solar winds overlaid with recent observations. The temperature and density of the slow wind case becomes larger on account of the larger \( \langle dv_{\perp,0}\rangle \), which explains the observations. On the other hand, smaller \( B_{r,0}/f_{tot} \) gives slower terminal speed. As a result, the observed anti-correlation of the wind speed and the coronal temperature (Schwadron and McComas, 2003) is well-explained by our simulations. In the slow wind case, the acceleration of the outflow is more gradual, and it is not negligible in \( r \gtrsim 20 R_\odot \) (e.g. Nakagawa et al., 2006).

The Alfvén wave dissipates more slowly in the fast wind conditions because of larger \( B_r(\propto B_{r,0}/f_{tot}) \). As a result, \( \langle dv_{\perp}\rangle \) is larger in the fast wind model. Various in situ observations in the solar wind plasma near the earth also show that the fast wind contains more Alfvénic wave components (see Tsurutani and Ho, 1999, for review), which can be explained via the nonlinear dissipation of Alfvén waves based on our simulations.

Although \( \langle dv_{\perp,0}\rangle \) and \( B_{r,0}/f_{tot} \) of the fast and slow winds are simply chosen to explain the observations, we would like

\[\text{\textcopyright T. K. Suzuki: Solar and stellar winds by nonlinear Alfvén waves)}\]
to discuss the difference of these parameters. Slow winds are mainly from low-latitude regions, which are mostly covered by closed regions. Then, open field regions in low-latitude regions generally expand more, namely \( f_{\text{tot}} \) is larger. This is an interpretation why \( B_0/f_{\text{tot}} \) is smaller in slow winds. Some solar winds are known from the vicinity of active regions (Kojima et al., 1999). Due to the influence from active regions, the amplitudes of the footpoint motions of these solar winds is expected to be larger than solar winds originating from coronal holes. We think that this leads to larger \((dv_{\perp,0})\) in slow winds.

3.5 Application to red giant winds

So far we have focused on the acceleration of solar wind. However, the same process is expected to operate in other types of stars that have surface convective layer, such as red giant stars, proto-stars, and intermediate and low mass main sequence stars. Red giant winds are studied in 1-D steady-state calculations (Hartmann and MacGregor, 1980) and 2-D dynamical simulations (Airapetian et al., 2000), although these studies do not set photosphere as the inner boundaries but arbitrary higher altitudes. We simulation red giant winds from the photosphere by extending the solar wind simulation (Suzuki, 2007).

We consider stellar winds from 1\(M_\odot\) stars in various evolutionary stages from main sequence to red giant branch. The properties of surface fluctuations (e.g. amplitude and spectrum) can be estimated from conditions of surface convection which depend on surface gravity and temperature (e.g. Renzini et al., 1977; Stein et al., 2004). Then, we carry out the simulations of the red giant winds in a similar manner to the solar wind simulations.

Figure 7 presents the evolution of stellar winds of a 1\(M_\odot\) star from main sequence to red giant stages. The middle panel shows that the average temperature drops suddenly from \(T \simeq 7 \times 10^5 \text{K}\) in the sub-giant star (blue) to \(T \leq 10^5 \text{K}\) in the red giant stars, which is consistent with the observed “dividing line” (Linsky and Haisch, 1979). The main reason of the disappearance of the steady hot coronae is that the sound speed \((\approx 150 \text{km s}^{-1})\) of \(\approx 10^6 \text{K}\) plasma exceeds the escape speed, \(v_{\text{esc}}(r) = \sqrt{2GM_*/r}\), at \(r \gtrsim \text{a few} \, R_\odot\) in the red giant stars; the hot corona cannot be confined by the gravity any more in the atmospheres of the red giant stars. Therefore, the material flows out before heated up to coronal temperature. In addition, the thermal instability of the radiating cooling function (Landini and Monsignori-Fossi, 1990) plays a role in the sudden decrease of temperature (Suzuki, 2007).

The top panel of Fig. 7 shows that nearly-static regions are formed above the photospheres in the red giant stars, and the acceleration of the winds essentially starts from several stellar radii. Accordingly, their wind speeds in the outer regions are considerably slower than the escape velocities at the surfaces, which is consistent with the observed trend (e.g. Dupree, 1986).
However, it is difficult to heat up protons which compose the main part of plasma because the energy of ion cyclotron waves that are resonantly coupled with protons are already absorbed by the heavy ions (Cranmer, 2000). Therefore, we believe that low frequency ($\lesssim 1$ Hz) Alfvén waves, which are focusing on in this paper, is more dominant in the total heating.

5 Conclusions

We have performed 1-D MHD numerical simulations of solar and stellar winds from the photosphere. The low-frequency Alfvén waves are generated by the footpoint fluctuations of the magnetic field lines. We have treated the wave propagation and dissipation, and the heating and acceleration of the plasma in a self-consistent manner. Our simulation is the first simulation which treats the wind from the real surface (photosphere) to the (inner) heliosphere with the relevant physical processes.

We have shown that the dissipation of the low-frequency Alfvén waves through the generation of the compressive waves (decay instability) and shocks (nonlinear steepening) is one of the solutions for the heating and acceleration of the plasma in the coronal holes. However, we need to carefully examine the validity of the 1-D MHD approximation we have adopted.

The density, and accordingly the mass flux, of solar winds show a quite sensitive dependence on $\langle dv_\perp, 0 \rangle$ because of an unstable aspect of the heating by the nonlinear Alfvén waves. For example, the mass flux of solar wind becomes $\sim 100$ times smaller if $\langle dv_\perp, 0 \rangle$ becomes $\simeq 1/2$. We also find that the solar wind speed has a positive correlation with $B_{r,0}/f_{\text{tot}}$, which is consistent with recent observations by Kojima et al. (2005).

Based on these findings, we show that both fast and slow solar winds can be explained by the single process, the dissipation of the nonlinear low-frequency Alfvén waves, with different sets of $\langle dv_\perp, 0 \rangle$ and $B_{r,0}/f_{\text{tot}}$. Our simulations naturally explain the observed (i) anti-correlation of the solar wind speed and the coronal temperature and (ii) larger amplitude of Alfvénic fluctuations in the fast wind.

We have also extended the solar wind simulations to red giant winds. With stellar evolution, the steady hot corona with temperature, $T \approx 10^6$ K, suddenly disappears because the surface gravity becomes small; hot plasma cannot be confined by the gravity. Nearly static regions are formed above the photospheres of the red giant stars, and the stellar winds are effectively accelerated from several stellar radii. Then, the wind velocity is much smaller than the surface escape speed, because it is regulated by the slower escape speed at that location.
